SUMMARY

An experimental investigation of the blade-vortex interaction impulsive noise characteristics of an advanced main rotor system for the UH-1 helicopter has been conducted. Models of both the advanced main rotor system and the standard or "baseline" UH-1 main rotor system were tested at one-quarter scale in the Langley 4- by 7-Meter (V/STOL) Tunnel using the General Rotor Model System (GRMS). Tests were conducted over a range of descent angles which bracketed the blade-vortex interaction phenomenon for a range of simulated forward speeds. The tunnel was operated in the open-throat configuration with acoustic treatment to improve the semi-anechoic characteristics of the test chamber. This investigation provided detailed acoustical data for these two rotor systems operating at similar flight conditions. These data are presented without analysis or discussion.

INTRODUCTION

Helicopter rotor noise is typically separated into categories, such as rotational noise, broadband turbulence interaction noise, and impulsive noise. When present, impulsive noise is usually the most objectionable for the community (refs. 1, 2, & 3) and represents a significant problem for reducing ground detectability of military helicopters. Impulsive noise can occur during high-speed flight as a result of the relatively high advancing blade tip Mach numbers or during partial power descents as a result of the interaction of a blade with a vortex generated by a prior blade passage.

Advanced composite technology has permitted application of planform variation, high twist, and advanced airfoils on existing and new rotor systems (refs. 4 & 5). Such a rotor has been proposed for the UH-1 to take advantage of the new freedom in blade design primarily to improve the aerodynamic performance of the UH-1 in hover and forward flight. The design methodology indicated a substantial aerodynamic performance benefit was possible. An aerodynamic performance analysis of the results of a model rotor test (ref. 6) verified that the advanced rotor system (ARS) provided an improvement in rotor system efficiency of 10 percent in hover and as much as a 17 percent reduction in required torque in forward flight when compared with the "baseline" or standard rotor system (SRS). Acoustic analysis of the in-plane high-speed impulsive noise (ref. 7) demonstrated that a 7 to 8 dB reduction in noise generation is available by using the ARS on the UH-1 helicopter. The data presented herein were collected to evaluate the effect of the advanced rotor design on the blade-vortex interaction (BVI) impulsive noise.

SYMBOLS AND ABBREVIATIONS

Symbols

A_1	first harmonic of lateral cyclic blade pitch, deg
a_0	rotor coning angle, fixed at 2.75°
a_{1s}	first harmonic of longitudinal flapping, deg
B_1	first harmonic of longitudinal cyclic blade pitch, deg
b_{1s}	first harmonic of lateral flapping, deg
C_Q	rotor torque coefficient, $\frac{\text{ROTOR TORQUE}}{\rho \pi R^3 (\Omega R)^2}$
C_T	rotor thrust coefficient, $\frac{\text{ROTOR THRUST}}{\rho \pi R^2 (\Omega R)^2}$
C	standard rotor system blade chord, 0.1334 m
D	rotor drag, Newtons
L	rotor lift, Newtons
R	rotor radius, 1.829 m
V_T	rotor blade-tip speed, knots
V_∞	free-stream velocity, knots
x, y, z	coordinates for microphone locations in tunnel, m
α	angle of attack of rotor shaft, deg
α_{Tpp}	rotor tip-path-plane angle of attack, referenced to tunnel geometric centerline, deg
γ	rotor descent angle, $\tan^{-1} (D/L)$
θ_C	rotor collective control angle, deg
μ	advance ratio, V_∞/V_T
ρ	local free-stream density, kg/m^3
Ω	rotor angular rotational velocity, rad/sec

Abbreviations

ARS	advanced rotor system
BVI	blade-vortex interaction
GRMS	general rotor model system
rpm	revolutions per minute
SP	sound pressure, dynes/cm ²
SPL	sound pressure level, dB (re. 0.0002 dynes/cm ²)
SRS	standard rotor system

HELICOPTER MODEL AND TEST FACILITY

Helicopter Model

The General Rotor Model System (GRMS) mounted in the 4- by 7-Meter (V/STOL) Tunnel was used for this investigation (ref. 8). The fuselage was a one-quarter scale model of the UH-1 helicopter mounted to the GRMS (see fig. 1) with a balance to provide independent fuselage load data. A sketch of the model is provided in figure 2 and shows the two rotor systems tested.

Both main rotor systems used for this investigation were mounted to a geometrically scaled version of the UH-1 helicopter hub. One rotor system was geometrically and dynamically scaled to the current UH-1 helicopter rotor configuration and is referred to herein as the SRS. These blades were made of a fiberglass/kevlar composite having a graphite/epoxy composite structural torque box. The aerodynamic contours were formed by means of an external fiberglass/epoxy shell with a nomex honeycomb core in the trailing edge. The other rotor system had a modified blade planform and was constructed with dynamic characteristics as close as possible to the SRS and is herein referred to as the ARS. These advanced rotor blades were wider in root chord compared to the standard rotor blades with a 3 to 1 taper ratio beginning at the 50-percent radius. Advanced rotorcraft airfoils (ref. 9) were used with thickness ratios ranging from 12-percent inboard to 8-percent at the tip. Construction was similar to that of the standard rotor blades with the exception of a styrofoam/balsa trailing edge core. A sketch of the two different rotor blade designs tested is shown in figure 3 while their dimensional characteristics are presented in table 1.

The rotor had a teetering hub with cyclic and collective pitch on the blades controlled by a swash plate driven by remotely controlled actuators.

Rotor teetering measurements were made at the teetering axis. The rotor was driven by a 67-KW electric motor through a transmission. The entire system (rotor, transmission, and motor) was mounted on a six-component strain-gage balance within the model to measure rotor forces and moments. Performance data from this balance were used to obtain the necessary aerodynamic conditions for this test including lift coefficient and simulated descent angle.

Wind-Tunnel Facility

The model investigation was conducted in the NASA Langley 4- by 7-Meter (V/STOL) Tunnel configured in the optional open-throat configuration. The dimensions of the rectangular jet entrance to the test chamber are 4.42 m high by 6.63 m wide. The ceiling height in the open-throat configuration was approximately 7.50 m above the test chamber floor. The model was supported in the wind-tunnel test section by a three-joint sting which allows model pitch and yaw control to plus or minus 45° about a fixed point on the model. The three-joint sting was mounted on a model support system which allowed height control as well as limited additional pitch and yaw control.

In order to improve the semi-anechoic characteristics of the test chamber, acoustic treatment was installed on the test section floor and ceiling. This acoustic treatment, which is partially visible in figure 4 and indicated in figure 5, consisted of fiberglass-filled aluminum panels and open-cell polyurethane foam. The 12.7 cm thick aluminum panels were installed on the floor directly under the model for a semi-rigid floor to facilitate periodic maintenance and modifications to the model rotor system. The 10.2 cm thick foam was installed on the floor directly up-stream of the aluminum panels and overhead on the surface of the raised ceiling. An evaluation of the effectiveness of this acoustic treatment is reported in reference 10.

Instrumentation

The acoustic transducers used for this investigation were 1.27 cm diameter condenser microphones fitted with standard nose cones. Eight microphones were positioned in the flow around the model. A rear-quarter-view photograph of the model installed in the tunnel with acoustical treatment is presented in figure 4 and shows the relative locations of six of the microphones. A sketch showing more detail of the relative position of all components in the test chamber (microphones, model, ceiling, entrance lip, treatment, etc.) is provided in figure 5.

Data from four of the eight microphones are presented in this paper. The locations of these four microphones relative to the rotor hub with the model at $\alpha = 0^\circ$ are presented in table II. Microphone 2, considered to be in the near-field, was mounted close to the fuselage under the rotor disk in a location shown to be relatively sensitive to BVI blade slap (refs. 11 and 12). Microphones 6, 7, and 8, considered to be in the far-field, were mounted upstream of the model as far as possible from the rotor, yet still in the free-field environment of the facility, at about 30° below the rotor tip-path-plane. The directivity of the BVI blade slap has been shown experimentally (ref. 13) and theoretically (ref. 14) to be a maximum in the direction of microphones 6, 7, and 8. Signals from each microphone were fed through an amplifier attenuator and into a 14-channel frequency-modulated (FM) tape recorder operating at 76.2 cm/sec tape speed. Blade azimuth and time-code were also recorded.

OPERATING PROCEDURES AND DATA REDUCTION

BVI impulsive noise has been shown to occur at partial-power descending flight. It was, therefore, necessary to determine the flight conditions (tunnel velocity and simulated descent angle) critical to BVI generation for each rotor system. At each tunnel velocity, with rotor operating at 1296 RPM, the simulated descent angle (computed from data obtained on the rotor balance only) was varied from a climb condition with no observable BVI through maximum BVI to a high descent angle where BVI was not observed. The rotor lift coefficient (defined as the rotor lift nondimensionalized by the product of rotor disk area, hover tip speed squared, and local free-stream density) was maintained as close as possible to 0.00315 during the first half of the investigation. During the latter half of the investigation the rotor lift coefficient was increased to 0.00365 in order to simulate the recent increases in gross weight of U.S. Army UH-1 helicopters.

The procedure used to establish each flight condition was to set a constant tunnel velocity equal to the desired flight speed, thus setting the advance ratio (μ). This was followed by adjusting the collective and cyclic controls to obtain the proper lift coefficient and zero teetering angle. While maintaining the desired lift coefficient and zero teetering, the model angle of attack was varied to encompass the range of simulated descent angles desired. With the rotor system at the desired condition, 30 seconds of information from the microphones were recorded on an FM tape recorder. Corresponding model and tunnel information were recorded simultaneously on the tunnel computer data acquisition system. Full aerodynamic performance characteristics corresponding to the acoustic data presented in this paper are listed in tables III and IV. Before and after the rotor tests, background noise

measurements were made at each speed tested with the blades off and the rotor hub turning at 1296 rpm.

Data Reduction, Correction, and Presentation

Corrections for jet-boundary and blockage effects were handled on-line to insure proper helicopter operating conditions and were computed in greater detail off-line for complete aerodynamic performance data reduction. The method used to correct the data is described in reference 15.

Before and after the tests, "pink noise" and "white noise" signals were recorded to verify that the complete system (excluding the microphones) had a flat frequency response over the range of interest (30 to 8000 Hz). All microphones were calibrated with a 124 dB piston phone at 250 Hz before and after each series of runs.

The acoustic data were analyzed for one-third-octave and narrowband sound pressure levels (SPL). The analyses used are described in references 16 and 17. The one-third-octave and narrowband spectra were obtained from a 2-second (43 rotor revolutions) digital record of each test condition. Each acoustic record was band-pass filtered at 30 to 10000 Hz and digitized at a rate of 1024 samples per rotor revolution in order to facilitate use of a fast Fourier transform technique (ref. 17). For the one-third-octave-band analysis, each record was divided into 40 blocks, each block corresponding to 1 rotor revolution (0.046 sec), thus providing 80 degrees of freedom for the confidence limits in the spectral estimate of the sound pressure level based upon the chi square random variable. Each record was triggered at the instant in time when the instrumented blade passed over the tail of the fuselage. The narrowband spectra were obtained by discrete Fourier transform of the 40 blocks in each record corresponding to 40 rotor revolutions. At the 80 percent confidence limits, the sound pressure estimates are accurate to within ± 15 percent of the

true value at each frequency based on the chi square random variable. The resolution in the frequency calculations of this analysis was one-half the blade passage frequency or approximately 21.7 Hz.

In each figure, one-third-octave spectra are presented for each microphone for various descent angles, all at constant tunnel velocities. Background noise one-third-octave spectra (blades off and hub turning) are provided for similar tunnel velocities. Sample pressure-time histories and narrowband spectra are included for each microphone. Two of each are presented for each one-third-octave plot--one with light or no discernable blade slap and one with the most intense blade slap. These data are presented in the following order without analysis:

8. Narrowband Analysis, Microphone No. 8 (h)

Background noise data indicate that the helicopter noise measured on microphones 2, 6, and 7 are well above background levels for most tunnel velocities tested. The exceptions are at the higher tunnel velocities for the higher frequencies only, where the background noise does contaminate the measured helicopter noise. Also, microphone 2 background noise contains a pure tone at about 1000 Hz while microphone 6 background noise contains a pure tone at about 5000 Hz. The helicopter noise measured at microphone 8 is heavily contaminated with background noise at all tunnel velocities for the higher frequencies and for all frequencies at the higher tunnel velocities. The reader should be careful in interpreting the generated helicopter noise for these cases and consider the effect of the background noise levels.

16. Abstract An experimental investigation of the blade-vortex interaction impulsive noise characteristics of an advanced main rotor system for the UH-1 helicopter has been conducted. Models of both the advanced main rotor system and the standard or "baseline" UH-1 main rotor system were tested at one-quarter scale in the Langley 4- by 7-Meter (V/STOL) Tunnel using the General Rotor Model System (GRMS). Tests were conducted over a range of descent angles which bracketed the blade-vortex interaction phenomenon for a range of simulated forward speeds. The tunnel was operated in the open-throat configuration with acoustic treatment to improve the semi-anechoic characteristics of the test chamber. This investigation provided detailed acoustical data for these two rotor systems operating at similar flight conditions. These data are presented without analysis or discussion.
